Infinitesimal and finite amplitude error propagation in spatially extended systems are numerically and theoretically investigated. The information transport in these systems can be characterized in terms of the propagation velocity of perturbations $V_p$. A linear stability analysis is sufficient to capture all the relevant aspects associated to propagation of infinitesimal disturbances. In particular, this analysis gives the propagation velocity $V_L$ of infinitesimal errors. If linear mechanisms prevail on the nonlinear ones $V_p=V_L$. On the contrary, if nonlinear effects are predominant finite amplitude disturbances can eventually propagate faster than infinitesimal ones (i.e., $V_p>V_L$). The finite size Lyapunov exponent can be successfully employed to discriminate the linear or nonlinear origin of information flow. A generalization of the finite size Lyapunov exponent to a comoving reference frame allows us to state a marginal stability criterion able to provide $V_p$ both in the linear and in the nonlinear case. Strong analogies are found between information spreading and propagation of fronts connecting steady states in reaction-diffusion systems. The analysis of the common characteristics of these two phenomena leads to a better understanding of the role played by linear and nonlinear mechanisms for the flow of information in spatially extended systems.

I. INTRODUCTION

It is well recognized that chaotic dynamics generates a flow of information in bit space: due to the sensitive dependence on initial conditions one has an information flow from “insignificant” digits towards “significant” ones [1]. In spatially distributed systems, due to the spatial coupling, one has an information flow both in bit space and in real space. The flow in bit space is typically characterized in terms of the maximal growth rate of infinitesimal disturbances (i.e., of the maximal Lyapunov exponent), while the spatial information flow can be measured in terms of the maximal velocity of disturbance propagation $V_p$ [2–5].

The evolution of a typical infinitesimal disturbance in low-dimensional systems is fully determined once the maximal Lyapunov exponent is known. The situation is more complicated in spatiotemporal chaotic systems, where infinitesimal perturbations can evolve both in time and in space. In this case a complete description of the dynamics in the tangent space requires the introduction of other indicators, e.g., the comoving Lyapunov exponents [6] and the spatial and the specific Lyapunov spectra [7].

Nevertheless, the complete knowledge of these Lyapunov spectra is not sufficient to fully characterize the irregular behaviors emerging in dynamical systems, this is particularly true when the evolution of finite perturbations is concerned. Indeed, finite disturbances, which are not confined in the tangent space, but are governed by the complete nonlinear dynamics, play a fundamental role in the erratic behaviors observed in some high-dimensional system [8–12]. A rather intriguing phenomenon, termed stable chaos, has been reported in Ref. [9]: the authors observed that even a linearly stable system (i.e., with $\lambda<0$) can display an erratic behavior with $V_p>0$.

The first attempts to describe nonlinear perturbation evolution have been reported in Ref. [13]. However, in these studies the analysis was limited to the temporal growth rate associated with second order derivatives of one dimensional maps. A considerable improvement along this direction has been recently achieved with the introduction of the finite size Lyapunov exponent (FSLE) [14]: a generalization of the maximal Lyapunov exponent able to describe also finite amplitude perturbation evolution. In particular, the FSLE has been already demonstrated useful in investigating high-dimensional systems [12].

The aim of this paper is to fully characterize the infinitesimal and finite amplitude perturbation evolution in spatiotemporal chaotic systems. Coupled map lattices (CML’s) [15] are employed to mimic spatially extended chaotic systems. The FSLE is successfully applied to discriminate the linear or nonlinear origin of information propagation in CML’s. Moreover, a generalization of the FSLE to comoving reference frame (finite size comoving Lyapunov exponent) allows us to state a marginal stability criterion able to predict $V_p$ in both cases: linear or nonlinear propagation. A parallel with front propagation in reaction-diffusion [16,17] (nonchaotic) systems is worked out. The analogies between the two phenomena authorize to draw a correspondence between “pulled” (“pushed”) fronts and linear (nonlinear) information spreading.

The paper is organized as follows. In Sec. II the FSLE is introduced and applied to low-dimensional systems (i.e., to single chaotic maps). Section III is devoted to the description and comparison of linear and nonlinear disturbance propagation observed in different CML models. The finite size co-
moving Lyapunov exponent is introduced in Sec. IV and employed to introduce a generalized marginal stability criterion for the determination of $V_p$. A discussion on information propagation in nonchaotic systems conclude Sec. IV. The analogies between disturbance propagation in chaotic systems and front propagation connecting steady states are analyzed in Sec. V. The Appendix is devoted to the estimation of finite time corrections for the computation of the FSLE in extended systems. Finally, some conclusive remarks are reported in Sec. VI.

II. FINITE SIZE LYAPUNOV EXPONENT: LOW-DIMENSIONAL MODELS

Let us introduce the FSLE by considering the dynamical evolution of the state variable $x=x(t)$ ruled by

$$\dot{x}(t) = f(x(t)),$$

where $f$ represents a chaotic flow in the phase space. In order to evaluate the growth rate of noninfinitesimal perturbations one can proceed as follows: reference $x(t)$ and perturbed $x'(t)$ trajectories are considered. The two orbits are initially placed at a distance $d(0) = \delta_{\text{min}}$, with $\delta_{\text{min}} \ll 1$, assuming a certain norm $d(t) = ||x'(t) - x(t)||$. In order to ensure that the perturbed orbit relaxes on the attractor a first scratch integration is performed for both the orbits until their distance has grown from $\delta_{\text{min}}$ to $\delta_0$ (where $1 \gg \delta_0 \gg \delta_{\text{min}}$). This transient ensures also the alignment of the perturbation along the direction of maximal expansion. Then the two trajectories are let to evolve and the growth of their distance $d(t)$ through different preassigned thresholds $(\delta_n = \delta_0 r^n, \text{with } n = 0, \ldots, N)$ and typically $1 < r \approx 2$ is analyzed.

After the first threshold, $\delta_0$, is attained the times $t \approx \delta_n(r)$ required for $\delta(t)$ to grow from $\delta_n$ up to $\delta_{n+1}$ are registered. When the largest threshold $\delta_N$ (which should be obviously chosen smaller than the attractor size) is reached, the perturbed trajectory is rescaled to the initial distance $\delta_{\text{min}}$ from the reference one.

By repeating the above procedure $N$ times, for each threshold $\delta_n$, one obtains a set of ‘doubling’ times (this terminology is strictly speaking correct only if $r = 2$) \{$(\tau_n, r)$\}$_{i=1, \ldots, N}$ and one can define the average of any observable $A = A(t)$ on this set of doubling times as:

$$\langle A \rangle_r = \frac{1}{N} \sum_{i=1}^{N} A_i,$$

where $A_i = A(\tau_n, r)$. The average $\langle \cdot \cdot \cdot \rangle_r$ does not coincide with an usual time average $\langle \cdot \cdot \rangle_t$ along a considered trajectory in the phase space, since the doubling times typically depend on the considered point along the trajectory and on the threshold $\delta_n$. The two averages are linked (at least in the continuous case) via the following straightforward relationship [18]:

$$\langle A(t) \rangle_r = \frac{1}{T} \int_0^T \langle A(\tau) \rangle_r d\tau, \quad (1)$$

where $T = \sum_{i=1, N} \tau_i(\delta_n, r)$ and $\langle \tau(\delta_n, r) \rangle_r = T/N$.

A natural definition of the finite size Lyapunov exponent $\lambda(\delta_n)$ is the following [14]:

$$\lambda(\delta_n) = \frac{1}{\langle \tau(\delta_n, r) \rangle_r} \ln r = \frac{1}{\langle \tau(\delta_n, r) \rangle_r} \ln r. \quad (2)$$

The last equality stems from the relationship among the two averages reported in Eq. (1).

In the limit of infinitesimal perturbation $\delta_n$ and of infinite $T$ (or $N$) the FSLE converges to the usual maximal Lyapunov exponent

$$\lim_{N \to \infty} \lim_{\delta_n \to 0} \lambda(\delta_n) = \lambda. \quad (3)$$

In practice, at small enough $\delta_n$, $\lambda(\delta_n)$ displays a plateau $\sim \lambda$. Moreover, one can verify that $\lambda(\delta_n)$ is independent of $r$, at least for not too large $r$ [14].

In Eq. (2) continuous time has been assumed, but discrete time is the most natural choice when experimental data sets (typically sampled at fixed intervals) are considered. In order to generalize the FSLE’s definition to the case of discrete time dynamical systems, let us consider the following map:

$$x(t+1) = F(x(t)),$$

where $x$ is a continuous variable, and $t$ assumes integer values. In this case $\tau(\delta_n, r) = \tau$ has simply to be interpreted as the minimum ‘integer’ time such that $\delta(\tau) \gg \delta_{n+1}$, and, since now $\delta(\tau)/\delta_n$ is a fluctuating quantity, the following definition is obtained:

$$\lambda(\delta_n) = \frac{1}{\langle \tau(\delta_n, r) \rangle_r} \ln \left( \frac{\delta(\tau)}{\delta_n} \right). \quad (4)$$

A theoretical estimation of Eq. (4) is rarely possible, and in most cases, one can only rely on a numerical computation of $\lambda(\delta_n)$. However, in the following we will report two simple cases for which an approximate analytic expression for the FSLE can be worked out.

Let us first consider the tent map

$$F(x) = 1 - 2 |x - \frac{1}{2}|,$$

where $x \in [0:1]$. This is a one-dimensional chaotic map, since $\lambda = \ln 2$ is positive.

Due to the simplicity of this map, one can estimate the expression (4) analytically obtaining the following approximation:

$$\lambda(\delta) \approx \ln 2 - \delta, \quad (5)$$

valid for not too large $\delta$ values. The maximal Lyapunov exponent is correctly recovered in the limit $\delta \to 0$ and the above expression reproduces quite well the numerical estimate of the FSLE [see Fig. 1(a)]. An important point to stress is that for this map the finite amplitude perturbations grow with the same rate or slower than the infinitesimal...
ones. The contraction of perturbations at large scales is due to saturation effects related to the attractor size. A similar dependence of the FSLE on the considered scale is observed for the majority of the chaotic maps (logistic, cubic, etc.), as we have verified.

One can wonder if there are systems for which, at variance with the behavior (5), the finite size corrections lead to an enhancement of the growth rate at large scales. As shown in Ref. [11], the shift map $F(x) = \beta x$ mod 1 represents a good candidate. Also in this case it is possible to obtain an analytical expression for the FSLE, when $\delta \leq [1/(r + \beta)]$,

$$
\lambda(\delta) = \frac{1}{1 - \delta} \left( (1 - 2\delta) \ln \beta + \delta \ln \left( \frac{1 - \beta \delta}{\delta} \right) \right),
$$

(6)

which again correctly reproduces the numerical data [see Fig. 1(b)] and in the limit $\delta \to 0$ reduces to the corresponding maximal Lyapunov exponent $\lambda = \ln \beta$. As expected, finite amplitude disturbances can grow faster than infinitesimal ones:

$$
\lambda(\delta_0) > \lambda(\delta \to 0) = \lambda \quad \text{for} \quad 0 < \delta \lesssim \delta_0,
$$

(7)

where $\delta_0$ indicates the threshold at which saturation effects set in. An even more interesting situation is represented by the circle map $F(x) = \alpha + x$ mod 1. This map is marginally stable (i.e., $\lambda = 0$), but it is unstable at finite scales. Indeed, the FSLE is given by $\lambda(\delta) = \delta/(1 - \delta) \ln[(1 - \beta \delta)/\delta]$, which is positive for $0 < \delta < 1/2$. Therefore at small, but finite, perturbations a positive growth rate is observed in spite of the (marginal) stability against infinitesimal perturbations. As a consequence, the circle map can exhibit behaviors that can be hardly distinguished from chaos under the influence of noise, since small perturbations may be occasionally driven into the nonlinear (unstable) regime and therefore amplified. Of course, the role of noise can be played by coupling with other maps, e.g., it has been found that coupled circle maps display behavior resembling (for some aspects) that of a chaotic system [11]. This phenomenon becomes even more striking in certain coupled stable maps where, even if the maximal Lyapunov exponent is negative [9], one can have a strong sensitivity to noninfinitesimal perturbations [19] (see Sec. IV B for a detailed discussion).

The two maps here examined for which Eq. (7) holds have a common characteristic: they are discontinuous. However, in order to observe similar strong nonlinear effects, it is sufficient to consider a continuous map with high, but finite, first derivative $|F'|$ values [10]. In this respect a simple example, that will be examined more in detail in Sec. IV, is represented by the map

$$
F(x) = \begin{cases} 
bx, & 0 \leq x < 1/b, \\
1 - c(1 - q)(x - 1/b), & 1/b \leq x < b/c, \\
q + d(x - b/c), & b/c \leq x \leq 1;
\end{cases}
$$

(8)

with $b = 2.7$, $d = 0.1$, $q = 0.07$, and $c = 500$. For $c \to \infty$ the map (8) reduces to the one studied in Ref. [9]. For the map (8) the FSLE dependence on $\delta$ is similar to that observed for the shift map.

III. INFORMATION SPREADING IN SPATIALLY DISTRIBUTED SYSTEMS

In this section we will examine the mechanisms behind the information flow in spatially distributed systems. In particular, the influence of linear and nonlinear effects on information (error) spreading will be analyzed. As a prototype of spatially distributed system coupled map lattices (CML’s) [15] are considered:

$$
x_i(t+1) = F(\bar{x}_i(t))
$$

(9)

$$
\bar{x}_i(t) = (1 - \epsilon)x_i(t) + \frac{\epsilon}{2}(x_{i-1}(t) + x_{i+1}(t)),
$$

where $t$ and $i$ are the discrete temporal and spatial indices, $L$ is the lattice size ($i = -L/2, \ldots, L/2$), $x_i(t)$ the state variable, and $\epsilon \in [0:1]$ measures the strength of the diffusive coupling. $F(x)$ is a nonlinear map of the interval ruling the local dynamics.

In order to understand how the information spreads along the chain, let us consider two replicas of the same system, $x(t) = \{x_i(t)\}$ and $x'(t) = \{x'_i(t)\}$, that initially differ only in a single site of the lattice (e.g., $i = 0$) of a quantity $d_0$, i.e.,

$$
|x'_i(0) - x_i(0)| = \Delta x_i(0) = d_0 \delta_{i,0},
$$

(10)
It has to be stressed that the full nonlinear dynamics contribute to the evolution of $\Delta x_i(t)$. The spreading of this initially localized disturbance can be characterized in terms of the velocity of information propagation $V_p$ [2,4]. As shown in Fig. 2, $\Delta x_i(t)$ can grow only within a light cone, determined by $V_p$. For velocities higher than $V_p$, the disturbance is instead damped. This individuates a sort of predictability “horizon” in space-time, i.e., an interface separating the perturbed from the unperturbed region.

The velocity $V_p$ can be directly measured by detecting the leftmost $i_l(t)$ and the rightmost $i_r(t)$ sites for which at time $t$ the perturbation $\Delta x_i(t)$ exceeds a preassigned threshold. The definition of $V_p$ is the following:

$$V_p = \lim_{t \to \infty} \lim_{L \to \infty} \frac{i_r(t) - i_l(t)}{2t},$$

where the limit $L \to \infty$ has to be taken first to avoid boundary effects. The velocity (12) does not depend on the chosen threshold values [2,4,10].

Since the dynamics of the difference field (11) is not confined in the tangent space, non linearities can play a crucial role in the information propagation. Indeed, we will see that the evolution of the disturbances strongly depend on the considered map $F(x)$ and in particular on the shape of $\lambda(\delta)$. In the next subsection propagation in CML’s with local chaotic maps for which $\lambda(\delta) \approx \lambda \forall \delta$ is discussed. Local maps for which the condition (7) holds will be the subject of Sec. III B.

A. Linear mechanisms

Since in this subsection we consider CML’s for which the local instabilities are essentially dominated by the behavior of infinitesimal perturbations, most of the features can be understood by limiting the analysis to the tangent space. The evolution in tangent space is obtained by linearizing Eq. (9), i.e.,

$$\delta x_i(t+1) = F'(\tilde{x}_i(t)) \left[ \delta x_i(t) + \frac{\epsilon}{2} \left( \delta x_{i+1}(t) - \delta x_{i-1}(t) \right) - 2 \delta x_i(t) \right],$$

where $F'$ is the first derivative of a one-dimensional chaotic map. Let us again consider as initial condition for the evolution of Eq. (13) a localized perturbation as Eq. (10) with $d_0$ infinitesimal. The spatiotemporal dynamics of the tangent vector $\{\delta x_i(t)\}$ is determined by the interaction and competition of two different mechanisms present in Eq. (13): the chaotic instability and the spatial diffusion.

As a first approximation, the effects of the two mechanisms can be treated as independent. The chaotic instability leads to an average exponential growth of the infinitesimal disturbance $|\delta x_0(t)| \approx d_0 \exp(\lambda t)$. On the other hand, the spatial diffusion, due to the coupling, approximately leads to a spatial Gaussian spreading of the disturbance: $|\delta x_i(t)| \approx |\delta x_0(t)| \sqrt{\frac{4\pi D t}{\epsilon t^2}} \exp(-\frac{\epsilon t^2}{4Dt})$, where $D = \epsilon/2$. Combining these two effects one obtains

$$|\delta x_i(t)| \approx d_0 \frac{1}{\sqrt{2\pi\epsilon t}} \exp\left(\lambda t - \frac{\epsilon t^2}{2\epsilon t}\right).$$

Since the chaotic nature of the phenomenon will typically induce fluctuations, Eq. (14) can only describe the average shape of the disturbance. Moreover, Eq. (14) holds only when the perturbation is infinitesimal, since when the disturbance reaches finite values a saturation mechanism (due to the nonlinearities) sets in preventing the divergence of $|\delta x_i(t)|$.

To verify the validity of Eq. (14), we studied the evolution of localized perturbations of a homogeneous spatiotemporal chaotic state, in particular coupled logistic and tent maps have been considered in the regime of “fully developed turbulence” [2]. First, the system is randomly initialized and let to relax for a relatively long transient. At this stage two replicas of the same system are generated and to one of the two a localized perturbation [as in Eq. (10)] is added. The evolution of the difference field (11) is then monitored at successive times. In order to wash out the fluctuations, the shape of the disturbance is obtained averaging over many distinct realizations.

As one can see from Fig. 3, Eq. (14) is fairly well verified for large enough coupling while it fails at small $\epsilon$ [20]. These discrepancies are due to the finite spatial resolution (that in CML’s is always fixed to 1), since for small diffusivity constant the discretization of the Laplacian becomes inappropriate. The expression (14) for disturbance evolution has been already proposed in Ref. [21] for CML’s in two dimensions. Deviations from Eq. (14) have been observed also in Ref. [21], but attributed to anomalous diffusive behaviors. It has to be remarked that expression (14) is valid only at short times, since asymptotically ($t \to \infty$) the infinitesimal disturbance will be damped by the spatial diffusion.
tesimal leading edge of the propagating front $|\delta x_i(t)|$ assumes an exponential profile \([11]\).

For what concerns the propagation velocity, an estimation of \(V_p\) can be obtained for infinitesimal perturbations by the evaluation of the so-called maximal comoving Lyapunov exponents \(\Lambda(\nu)\) \([6]\). The time evolution of an initially localized (infinitesimal) disturbance \((10)\) in a reference frame moving with velocity \(v\) can be expressed as

\[
|\delta x_i(t)| \sim d_0 e^{\Lambda(\nu) t},
\]

by following the perturbation along the world line \(i = vt\) one can easily measure the corresponding comoving Lyapunov exponent \(\Lambda(\nu)\) (for more details see Refs. \([6,22]\)). The information propagation velocity is the maximal velocity for which a disturbance still propagates without being damped. Therefore it can be defined through the following marginal stability criterion \([6]\):

\[
\Lambda(V_L) = 0,
\]

where the velocity has been now indicated with \(V_L\) in order to stress that it has been obtained via a linear analysis. For the maps considered in this section the identity \(V_p = V_L\) is always fulfilled.

As shown in Ref. \([6]\), in a closed system with symmetric coupling \(\Lambda = \Lambda(\nu)\) has typically a concave shape, with the maximum located at \(\nu = 0\) [in particular \(\lambda = \Lambda(\nu = 0)\)]. An approximate expression can be obtained for \(\Lambda(\nu)\) by substituting \(i = vt\) in Eq. \((14)\) and by comparing it with Eq. \((15)\):

\[
\Lambda(\nu) = \lambda - \nu^2/2\varepsilon.
\]

This parabolic expression for \(\Lambda(\nu)\) suffers of the same limits mentioned for the Gaussian approximation \((14)\) for the disturbance evolution. Anyway, from Eq. \((17)\) an analytical prediction can be obtained for \(V_L\):

\[
V_L = \min_{\nu} \frac{\lambda(\nu)}{\mu} \equiv \frac{\lambda_L}{\mu_L},
\]

where \(\mu_L\) and \(\lambda_L = \lambda(\mu_L)\) represent the spatial decay rate and the temporal growth rate of the leading edge, respectively. The expression \((20)\) for the linear velocity is identical
to the one derived for propagation of fronts connecting a stable to an unstable steady state [23].

B. Nonlinear mechanisms

In this section we investigate the case of coupled maps for which \( \lambda (\delta) > \lambda (0) \) in some interval of \( \delta \). As noticed in Sec. II, this behavior can be observed in chaotic (absolutely unstable) maps, as well as in stable and marginally stable maps. Let us first analyze chaotic maps, nonchaotic ones will be discussed in Sec. IV B.

For these systems it is possible to have \( V_p > V_L \), this means that the disturbance can still propagate also in the velocity range \( [V_L, V_p] \), even if the corresponding comoving Lyapunov exponents are negative. Therefore, the linear marginal stability criterion (16) does not hold anymore. We want to stress that the condition (7) is necessary, but not sufficient to ensure that \( V_p > V_L \), since all the details of the coupled model play also an important role.

In Fig. 5 the spatiotemporal evolution of an initially localized disturbance of a chain of coupled shift maps is reported. As shown in Ref. [24], when the coupling \( \varepsilon \ll 1/2 \) the maximal Lyapunov exponent for such model coincides with that of the single map [namely, \( \lambda = \ln(\beta) \)] and if \( \beta > 1 \) the system is chaotic. Initially the perturbation, that is still infinitesimal, spreads with the linear velocity \( V_L \) above defined. At later time it begins to propagate faster with a velocity \( V_p > V_L \). Comparing Fig. 5 with Fig. 2, one can see that the second stage of the propagation sets in when the bulk of the perturbed region reaches sufficiently high values. As a matter of fact the initial stage of propagation disappears if we initialize the two replicas with a disturbance of amplitude \( O(1) \). From these facts it is evident that the origin of the information propagation characterized by \( V_p > V_L \) should be due to the strong nonlinear effects present in this type of CML.

The behavior at long times can be understood by considering the dependence of \( \lambda (\delta) \) on the disturbance amplitude as shown in Fig. 1(b): actually the figure refers to the single map with \( \beta = 2 \), but the shape of \( \lambda (\delta) \) is qualitatively the same also for the coupled system and for other \( \beta \) values. Until the perturbation is infinitesimal \( \lambda (\delta) = \lambda \) and the linear analysis applies, when the disturbance becomes bigger than a certain amplitude \( \delta^{NL} \) the growth will be faster, since now

\[
\lambda (\delta) > \lambda. \]

As it can be clearly seen in Fig. 6, the perturbation is well reproduced by the linear approximation (14) until the amplitude of the perturbation reaches a critical value \( \delta^{NL} \sim O(10^{-4}) \) above which the nonlinear effects set in. At this stage the nonlinear instabilities begin to push the front leading to an increase of its velocity and deforming the profile of the perturbation. This becomes exponential at much shorter times than in the linear situation discussed in previous subsection. Moreover, when the propagation is dominated by nonlinear mechanisms the spatial decay rate \( \mu_{NL} \) of the asymptotic leading edge will be greater of the linear expected value \( \mu_L \): this result can be explained again invoking the analogy with propagation of fronts connecting steady states [11].

To better clarify the difference between the linear and nonlinear mechanisms we show the behavior of \( \Delta x_i (t) \)
along the world line \( i = V t \) for two different velocities: \( V_1 = 0 \) and \( V_2 < V_2 < V_p \). From Fig. 7, one observes for the zero-velocity situation an exponential increase of the perturbation with rate \( \lambda \) until it eventually saturates. For the case corresponding to velocity \( V_2 \) an initial exponential decay with rate \( \Lambda (V_2) \) is seen, followed at later times by a resurgence of the disturbance. The successive evolution of the perturbation is no more exponential and exhibits strong fluctuations. These features suggest that in order to generalize the criterion (16) to nonlinear driven information spreading the growth of finite amplitude perturbations in a moving reference frame should be analyzed.

IV. FINITE SIZE LYAPUNOV EXPONENT: EXTENDED SYSTEMS

In this section we introduce the finite size comoving Lyapunov exponent (FSCLE) that is a generalization of the FSLE to a moving reference frame. First of all let us define the FSLE for an extended system: in this case exactly the FSLE to a moving reference frame should be analyzed. Thus a nonlinear front is excited and this invades the linear mechanism characterized by \( \Lambda (\delta, v) \), but as soon as in the central site \( \delta > \delta_{\text{NL}} \) the nonlinear mechanism begins to be active. Thus a nonlinear front is excited and this invades the linear region propagating with a velocity higher than \( V_L \), therefore the higher is \( v \) the smaller is the scale at which nonlinear effects are observed.

In the interval \( V_L < v \leq V_p \) [see Fig. 8(b)], \( \Lambda (\delta, v) \) is still positive and its maximal value decreases for increasing \( v \).

\[
\Lambda (\delta, v) = \frac{1}{(\pi \delta)^{1/2}} \text{exp} \left( \frac{\int \left( \frac{\Delta (\delta)}{\delta} \right) \delta_{n}}{\epsilon} \right) ,
\]

where the dependence on the velocity \( v \) derives from the employed norm (23). Note that we have used Eq. (4) due to the discreteness of the temporal evolution. In the limit of very small perturbation the FSCLE reduces to the comoving Lyapunov exponent

\[
\lim_{\delta \to 0} \Lambda (\delta, v) = \Lambda (v),
\]

and, for \( v = 0 \) one has the FSLE \( \lambda (\delta) \).

Actually there are finite time effects which prevents the limit (25) to be correctly attained. This is related to the fact that the FSCLE’s can be obtained only via finite time measurements. In the Appendix we show how one can include such finite time corrections.

In the next subsections we will give evidences that the marginal linear stability criterion (16) can be generalized with the aid of the FSCLE in the following way:

\[
\max_{\delta} \{ \Lambda (\delta, v) \} = 0 \quad \text{for} \quad v > V_p ,
\]

where \( V_p \) can be either \( V_L \), if the information propagation is due to linear mechanisms, or greater than \( V_L \), when nonlinear mechanisms prevail on the linear ones. For \( v > V_p \) one has \( \Lambda (\delta, v) = 0 \), since due to the definition of the FSCLE negative growth rate appear to be 0.

A. Chaotic systems

Let us first consider chaotic systems for which \( V_p = V_L \), in this case

\[
\max_{\delta} \{ \Lambda (\delta, v) \} = \Lambda (v)
\]

and the generalized criterion (26) reduces to the linear one (16). As already stressed in Sec. III B, shift coupled maps represent a prototype of the class of chaotic models for which \( V_p \) can be eventually bigger than \( V_L \). For this model the behavior of \( \Lambda (\delta, v) \) for various velocities is reported in Fig. 8.

For \( v < V_L \), we observe that \( \Lambda (\delta, v) \sim \Lambda (v) \) up to a certain value of the disturbance amplitude \( \delta_{\text{NL}} \), above which the FSCLE increases and exhibits a clear peak at some higher \( \delta \) value. From Fig. 8(a) it is clear that \( \delta_{\text{NL}} \) (which denotes the set in of the regime dominated by nonlinear mechanisms) decreases for increasing velocities and finally vanishes at \( v = V_L \). This behavior is reasonable since, as shown in Fig. 5, initially the disturbance evolves along the chain following the linear mechanism characterized by \( \Lambda (v) \), but as soon as in the central site \( \delta > \delta_{\text{NL}} \) the nonlinear mechanism begins to be active. Thus a nonlinear front is excited and this invades the linear region propagating with a velocity higher than \( V_L \), therefore the higher is \( v \) the smaller is the scale at which nonlinear effects are observed.

In the interval \( V_L \leq v \leq v_p \) [see Fig. 8(b)], \( \Lambda (\delta, v) \) is still positive and its maximal value decreases for increasing \( v \).
FIG. 8. $\Lambda(\delta, v)$ as a function $\delta$ for various velocities. The data refer to the coupled shift maps with $\beta=1.1$ and $\varepsilon=1/3$, with these parameters $V_L=0.250$ and $V_p=0.342$. In (a) results for velocities $v<V_L$ are reported, namely (from top to bottom), $v=0$, $v=0.10$, and $v=0.16$. The straight lines indicate $\Lambda(v)$. In (b) velocities in the range $[V_L,V_p]$ are reported, from the top $v=0.25$, $v=0.286$, $v=0.30$, $v=0.33$, $v=0.34$. Chains of lengths from $L=10^4$ up to $L=10^6$ have been employed and the statistics is over $2 \times 10^3$ doubling times.

The FSCLE vanishes for $v=V_p$ as Fig. 9(a) shows. In this velocity range $\Lambda(v)$ is always negative, therefore the instabilities observed in a reference frame moving with velocity higher than $V_L$ have a fully nonlinear origin. The residual fluctuations present in $\Lambda(\delta, v)$ are essentially due to the limited statistics. Indeed the nonlinear growth as shown in Fig. 7 is extremely fluctuating.

In Fig. 9(a) the dependence of $\max_{\delta}\Lambda(\delta, v)$ on $v$ for coupled shift maps is reported, as expected it vanishes exactly for $v=V_p$. For $v<V_L$ a nonmonotone behavior of $\max_{\delta}\Lambda(\delta, v)$ is observable, this is probably due to the complex interplay of linear and nonlinear effects. For $v>V_L$, the behavior is smoother and a monotone decrease is observed. As discussed in Sec. II, the discontinuity present in the shift map is not necessary in order to observe nonlinear mechanisms prevailing on linear ones.

As an example of continuous map exhibiting an information propagation velocity $V_p>V_L$ the map (8) is considered.

This type of CML has been already studied in Ref. [10]: it has been observed that in a certain parameter range $V_p$ can be finite even if the map is nonchaotic. Moreover, also in the chaotic regime there is a window of parameters where $V_p>V_L$, with our parameters choice $\Lambda \approx 0.182>0$.

Also in the present case we observe an overall behavior of the FSCLE resembling the one of the coupled shift maps. The main point that we want to remark is that in the limit $v \rightarrow V_p$, $\Lambda(\delta, v) \rightarrow 0$, as shown in Fig. 9(b). At variance with the shift map (that is an everywhere expanding map) the considered map shows contracting and expanding intervals. Therefore the disturbances during their spatiotemporal evolution can be alternatively expanded or contracted. This leads to strong fluctuations in the FSCLE values, that are difficult to remove.

As a matter of fact we observed that even for velocities slightly larger than $V_p$, $\Lambda(\delta, v)$ can be nonzero. But the sta-
tistics of these anomalous fluctuations is extremely low, referring to the parameters reported in Fig. 9(b) for \( v = 0.6 > V_p = 0.59 \) we observed an expansion (instead of the expected contraction) of disturbances in the 0.5\% of the studied cases. For higher velocities \( \Lambda(\delta, v) \) is zero for any considered \( \delta \).

B. Nonchaotic systems

On the basis of the linear analysis discussed in Sec. III A the propagation of disturbances should be present only in chaotic systems. For nonchaotic ones \( \lambda < 0 \) and from Eq. (16) one trivially obtains \( V_L = 0 \). On the other hand, in the class of systems for which \( \lambda(\delta) = \lambda \) there are also stable and marginally stable systems. Therefore, a propagation due solely to nonlinear terms can still be present for marginally stable systems. Therefore, a propagation due to nonlinear terms can still be present [9–11]. In this section we want to discuss the possible employ of the FSLE to characterize these maps.

Before entering into the description of the FSLE computation in such systems, it is of interest to recall an important phenomenon which appears in stable systems: the so-called “stable chaos” phenomenon [9]. Stable systems asymptotically evolve towards trivial attractors (i.e., fixed points, periodic, or quasi-periodic orbits). However, in spatially extended systems it may happen that the time needed to reach the asymptotic state is very long: it has been found that in certain stable CML the transient time diverges exponentially with the number of elements of the chain [8]. Moreover, this transient is characterized by a quasistationary behavior allowing for the investigation of the properties of the model with statistical consistency. In Ref. [9] it has been shown that a chain of coupled maps of the type (8), considered in their discontinuous limit (i.e., for \( c \rightarrow \infty \)), is nonchaotic but still exhibits erratic behaviors. This is associated to a non-zero information spreading within the system.

As far as the computation of the FSLE for these systems is concerned, some remarks are worth to be done. The definition of the FSLE in terms of error doubling times cannot be used in a straightforward manner to determine negative expansion rates. Another important point is that, at variance with the case of chaotic maps, finite perturbations should be now considered in order to observe an expansion.

These two points impede a straightforward implementation of our method to study these systems. Indeed, if one starts with too small perturbations the propagation does not manifest, while if one initializes the system with a finite perturbation \( \lambda(\delta) \) cannot be estimated with the required accuracy. Indeed, the only way to have an independence of \( \lambda(\delta) \) from the initial conditions is to initialize the system with infinitesimal perturbations and then to follow them until they become finite due to the dynamics of the system (see Ref. [14] for a detailed discussion).

The coupled (8) maps for \( c \rightarrow \infty \) have been recently analyzed by Letz and Kantz [19] in terms of an indicator similar to the FSLE (i.e., able to quantify the growth rate of non-infinitesimal perturbations). This indicator turns out to be negative for infinitesimal perturbations and becomes positive for finite perturbations. This means that a finite perturbation of sufficient amplitude can propagate along the system due to nonlinear effects. This confirms what was previously observed in Ref. [11] for marginally stable systems.

In Fig. 10 we show the behavior of a quantity \( I(\delta_n) \) similar to \( \lambda(\delta_n) \) which has been obtained as follows. We considered two trajectories at an initial distance \( \delta_n \), after one time step evolution the distance \( \delta \) between the trajectory is measured. Then one of the two trajectories is rescaled at a distance \( \delta_n \) from the other, keeping the direction of the perturbation unchanged, and the procedure is repeated several times and for several values of \( \delta_n \). Then we averaged \( \ln(\delta/\delta_n) \) over many different initial conditions obtaining \( I(\delta_n) \). For \( \delta_n \rightarrow 0 \), this is nothing but the usual algorithm for computing the maximal Lyapunov exponent [25].

As discussed in Ref. [14] this method suffers from the problem that when \( \delta_n \) is finite one is not able to correctly sample the measure on the statistically stationary state. Indeed a finite perturbation will generically bring the trajectory out from the “attractor.” Nevertheless the result is in good agreement with the one obtained in Ref. [19] and confirms that at the origin of the perturbation propagation in this system there should be a mechanism very similar to the one discussed for the shift map. Further studies related to the “stable chaos” phenomenon have been recently performed [26].

V. ANALOGIES WITH FRONT PROPAGATION IN REACTION DIFFUSIONS SYSTEMS

The perturbation evolution in spatially distributed systems can be described as the motion of an interface separating perturbed from unperturbed regions. In this spirit, one can wonder if and to what extent it is possible to draw an analogy between the evolution of this kind of interface and the propagation of fronts connecting steady states in reaction diffusion systems. As already noticed in Ref. [11], the two phenomena display many similarities. In the following we will discuss the similarities and differences, in particular we will introduce a simple phenomenological model which can help us in highlighting the analogies.

Let us start by recalling the basic features of fronts propagation in reaction diffusion systems with reference to the...
Fisher-Kolmogorov-Petrovsky-Piscounov (FKPP) equation [16]
\[
\partial_t \theta(z,t) = D \partial^2_{zz} \theta(z,t) + G[\theta(z,t)],
\]
where \(\theta(z,t)\) represents the concentration of a reactant which diffuses and reacts, the chemical kinetics is given by \(G(\theta)\). Typically the function \(G(\theta) \in C^1[0,1]\) with \(G(0) = G(1) = 0\) exhibits one stable (\(\theta = 1\)) and one unstable (\(\theta = 0\)) fixed point. Once the system is prepared on the stable state \([\theta(z) = 0 \forall z]\), an initial (sufficiently steep) perturbation [e.g., a step function \(\theta(z,t = 0) = \Theta(z - z_0)\)] will give rise to a smooth front moving with a velocity \(V_p\), that will connect the unstable and the stable fixed points: as a result the stable state will invade the unstable one. This equation admits many different traveling solutions that are typically characterized by their propagation velocities, however for a sufficiently steep initial perturbation of the unstable state the selected front is unique and its velocity \(V_p\) is bounded in the interval \([V_{\text{min}}, V_{\text{max}}]\), where
\[
V_{\text{min}} = 2 \sqrt{DG'(0)}
\]
and
\[
V_{\text{max}} = 2 \sqrt{D \sup_{0 < \theta < 1} \left| \frac{G(\theta)}{\theta} \right|},
\]
If \(G(\theta)\) is concave \(\sup_{0 < \theta < 1} \left[ \frac{G(\theta)}{\theta} \right]\) is attained at \(\theta = 0\) (i.e., \(\sup_{0 < \theta < 1} \left[ \frac{G(\theta)}{\theta} \right] = G'(0)\)) and the selected velocity is always the minimum one: the front is “pulled” by the growth of infinitesimal perturbations of the unstable state. Otherwise, if \(G(\theta)\) is convex one can observe a velocity \(V_p > V_{\text{min}}\): the front is now “pushed” by the growth of finite amplitude perturbations. These results are known as the Aronson and Weinberger theorem [27] (for more details see Ref. [17]). The velocity \(V_{\text{min}}\) can be easily obtained by performing a linear analysis of Eq. (27) and by employing a marginal stability criterion [23].

The subject of our analysis is the spreading of perturbations in a chaotic media. In order to compare our case with the FKPP, we should consider the time evolution of the difference of two chaotic trajectories \(\{\Delta x_i(t)\}_{i=1,\mathcal{L}}\). However, the nature of the two phases separated by the front is now different from the FKPP case. The interface separates an unstable \((\Delta x_i = 0)\) state from a “statistically stable” one. With the term “statistically stable” we mean that behind the front, in the bulk of the perturbed region \(\Delta x_i(t)\) does not converge to a stable fixed point (as for the FKPP) but it fluctuates in a stationary way around an average value. This suggests that a good model for reproducing this dynamical evolution would be a FKPP with a stochastic kinetics [28]. However, many similarities with FKPP can be established by neglecting the chaotic fluctuations and considering the average shape of the front [11]. In practice, this can be done by averaging the perturbation evolution over many different initial conditions.

Once the chaotic fluctuations are neglected, one can express the average perturbation growth in any site of the chain via the following mean-field approximation:
\[
u_i(t+1) = \exp(\lambda(\bar{\nu}_i(t)))\bar{\nu}_i(t),
\]
where \(i,t\) are the discrete space and time indices and \(\bar{\nu}_i = (1 - \varepsilon)u_i + \varepsilon I(2u_{i+1} + u_{i-1})\). Here, \(u_i(t)\) indicates the “average” \(\Delta x_i(t)\) and \(\lambda(u)\) the corresponding FSLE (at least for positive growth rates). In the limit \(u \to 0\) \(\lambda(u) \to \lambda\), while, for \(u \to 0\) one essentially recovers the model discussed in Ref. [29].

By passing to continuous variables is possible to show that Eq. (30) can be reduced to Eq. (27) (at least at the leading order). In order to transform Eq. (30) in its continuous version, let us introduce infinitesimal spatial and temporal resolutions \(dx\) and \(dt\), and assume that the diffusive scaling holds, i.e., \(dx^2 = dt\). Limiting to the first order expansion in \(dt\) (second order in \(dx\)), one easily shows that the continuous counterpart of Eq. (30) is
\[
\partial_t u = \lambda(u)u + \frac{\varepsilon}{2} \partial^2_x u,
\]
which is nothing but Eq. (27) with
\[
\lambda(u) = \frac{G(u)}{u},
\]
and \(D = \varepsilon/2\). As a consequence of the identity (32), one should observe a pulled dynamics for the chaotic front if \(\lambda > \lambda(u)\) \(\forall u \geq 0\), and a pushed one could occur only if \(\max_{\lambda} \lambda(u) > \lambda\). This can be considered as a reformulation of the Aronson and Weinberger theorem [27] in the context of information propagation. The velocity bounds (28)-(29) can be now identified with \(V_a = \sqrt{2\varepsilon K}\), i.e., Eq. (18), the first one and with
\[
V_s = \sqrt{2\varepsilon \max\{\lambda(u)\}}
\]
the second one. We stress again that the lower velocity bound is indeed represented by \(V_L\) and that it coincides with \(V_a\) only for sufficiently strong diffusive coupling \(\varepsilon\).

Another interesting point that we can investigate via a numerical simulation of the mean field effective equation (30) is the dependence of the propagation properties on the specific shape of \(\lambda(u)\). For instance, as previously conjectured, we expect that if a monotonic decreasing \(\lambda(u)\) is considered one should observe linear propagation, only. Indeed, numerical integrations of the model (30), with the choice \(\lambda(u) = A - Bu\), being \(A\) and \(B\) positive constants, show that \(V_s = V_a = \sqrt{2\varepsilon A}\), where \(A\) corresponds to the maximal Lyapunov of the effective model. A generalization of this simple model would require to consider \(A\) and \(B\) as fluctuating quantities generated by suitable stochastic processes. But while for the choice of \(A\) one can have some hint [29], this is not the case for \(B\).

Let us now consider the nonlinear propagation case, as we have previously seen a necessary condition in order to have \(V_p > V_L\) that is \(\max_{\lambda} \lambda(u) > \lambda\) for some finite \(u\). As for the

056201-10
the dynamics via Eqs. (30) and (34) as a function of $B=\ln(r_2)$, with $\varepsilon = 1/3$, $A = \ln 1.1$ and $C = A$. The threshold values are fixed to $\delta_{NL} = 10^{-3}$ and $\delta_{sat} = 0.53$ and a chain of $4 \times 10^3$ sites has been used.

The curves refer to $V_p = \sqrt{2\pi A}$ (solid line) and $V_r = \sqrt{2\pi B}$ (dashed line). Note that in the linear case $B < A$ there is perfect agreement between the measured velocity and the prediction.

The actual value of the selected velocity, this will depend on the value of the diffusive coupling and on the specific shape of $\lambda(u)$. In the following we will examine the dependence of $V_p$ on two quantities that characterize $\lambda(u)$: the difference $[\max_x \lambda(\delta) - \lambda]$ and the scale $\delta_{NL}$ at which the nonlinear effects set in.

As a first example let us consider $\lambda(u)$ as a step function:

$$\lambda(u) = \begin{cases} A, & 0 < u < \delta_{NL}, \\ B, & \delta_{NL} < u < \delta_{sat}, \\ -C, & u \geq \delta_{sat}, \end{cases}$$

where $A$, $B$, and $C$ are positive quantities, with $B > A$, while $\delta_{NL}$ and $\delta_{sat}$ are amplitude thresholds. The parameter $A$ is nothing but the Lyapunov exponent, $B$ mimics the nonlinear terms leading to an enhancement of the growth rate, and the last term mimics the damping of the perturbation due to the saturation effects. In Fig. 11 it is reported the behavior of the propagation velocity for the model (30) with $\lambda(u)$ given by Eq. (34) for various values of $B$, once $A$ and $C$ are fixed. From the figure is evident that if $B < A$ then $V_p = V_a$ (i.e., we are in the linear regime), while as soon as $B > A$ an increase of $V_p$ with respect to $V_a$ is observed.

In the whole examined parameter range $V_p$ is always reasonably approximated by $V_r$, but smaller. By increasing $B$ one observes an increase of the difference between the measured velocity and the linear prediction. These results confirm that the condition (7) is indeed a necessary condition in order to observe nonlinear propagation of information.

We will now investigate the role of $\delta_{NL}$ in determining the propagation velocity. It is quite obvious that modeling the dynamics via Eqs. (30) and (34) the nonlinear effects will disappear in the limit $\delta_{NL} \rightarrow \delta_{sat}$ and this is indeed confirmed by the simulations (see Fig. 12). In order to examine a less obvious situation, a modification of the expression (34) is also considered. In this second case $\delta_{sat} = \delta_{0} + \delta_{NL}$ is assumed, therefore by varying $\delta_{NL}$ the extension of the amplitude interval over which the nonlinear mechanism is active will not be modified (being fixed to $\delta_{0}$). But also in this second case $V_p \rightarrow V_a$ for increasing $\delta_{NL}$, this indicates that the smaller are the perturbation amplitudes affected by the nonlinear mechanisms the stronger will be the nonlinear effect on the velocity: $V_p \rightarrow V_a$ for $\delta_{NL} \rightarrow 0$.

Typically, in generic CML’s by varying a control parameter both the difference $[\max_x \lambda(\delta) - \lambda]$ as well as $\delta_{NL}$ will change. Moreover, even the definition of $\delta_{NL}$ for a continuous $\lambda(\delta)$ is not obvious. In order to understand the validity of the mean-field approximation (34) in a more realistic case we consider the shift map. In particular, for $\lambda(u)$ we employed the analytical expression (6) valid for the single uncoupled map.

The FSLE for coupled shift maps is actually different from Eq. (6), but we are neglecting correlations among different sites and effects due to the specific measure associated to the system. Nevertheless, a numerical integration of Eq. (30) equipped with Eq. (6) reproduces semiquantitatively the features observed for a lattice of coupled shift maps (see Fig. 13). In particular, also the simple mean-field model (30) with

---


the choice (6) is able to forecast the observed transition from nonlinear to linear behavior for $\beta \to 2$.

Concluding this section we can safely affirm that Eq. (30) is a reasonable model to mimic the perturbation evolution at a mean field level, neglecting the spatiotemporal fluctuations and correlations. In the same fashion $\lambda(u)$ can be considered as an “effective” nonlinear kinetics for the perturbation evolution.

VI. FINAL REMARKS

In this paper information (error) propagation in extended chaotic systems has been studied in detail. In particular, we have analyzed the relevance of linear and nonlinear mechanisms for the propagation phenomena in spatiotemporal chaotic coupled map lattices. Linear stability analysis is not always able to fully characterize disturbance propagation. This is particularly true for (marginally) stable systems with strong nonlinearities, where finite size perturbations are responsible for information spreading in the system. When the nonlinear effects prevail on the linear ones the propagation velocity of information $V_p$ can be higher than the linear velocity $V_L$. A necessary condition for the occurrence of information spreading induced by nonlinear mechanisms has been expressed in terms of the finite size Lyapunov exponent (FSLE). We have also shown the existence of strong analogies between error propagation and front propagation in reaction-diffusion models. In particular, the abovementioned necessary condition is analogous to the Aronson and Weinberger theorem [27] for front connecting stable and unstable steady states. In the linear and nonlinear case, the propagation velocity $V_p$ can be identified via an unique marginal stability criterion involving finite size Lyapunov exponents defined in a moving reference frame. This result generalizes the corresponding linear criterion expressed in terms of the maximal comoving Lyapunov exponents for the identification of $V_L$ [6].

These results can be of some interest for the synchronization and the control of extended systems. It has been recently shown that the synchronization of coupled extended systems is strongly influenced by nonlinear effects. In particular, the synchronization time exponentially diverges with the system size, even in nonchaotic situations, provided that $V_p > 0$ [30]. We believe that in these systems the appropriate indicator to characterize such transition would be the “transverse” Lyapunov exponent [31], once extended to finite scales. As far as control schemes are concerned, since they rely mainly on linear analysis [32], new nonlinear methods (e.g., based on the concept of FSLE’s) should be introduced in order to control the erratic behaviors due to fully nonlinear mechanisms.

A further aspect that should be addressed in future work concerns the extension of the applicability of the FSLE also to linearly stable systems: a candidate in this respect could be the indicator recently introduced in Ref. [19]. Finally, it is reasonable to expect that the present analysis is not limited to discrete models but that it can be applied to continuous extended systems described in terms of PDE’s, e.g., to the complex Ginzburg-Landau equation.

APPENDIX

In any numerical computation of the Lyapunov exponents one is forced to use a finite time approximation for an infinite time limit. Nevertheless, provided that the convergence to the asymptotic value is fast enough, this is not a dramatic problem. As a matter of fact, in low-dimensional systems very fast convergence to the asymptotic value is usually observed. However, this problem manifests more dramatically in high-dimensional systems, where the time to align along the direction of maximal expansion could be very long [29,33,34].

In the present case this problem is complicated by the fact that the FSLE is intrinsically a finite time indicator. Indeed the time a perturbation takes to grow from a value $\delta$ to $r_0 \delta$ is finite unless $\delta \to 0$. However, for the CML models here analyzed and for initially localized perturbation (10) it is possible to evaluate the corrections to apply to the FSLs, estimated at finite time, in order to recover, for sufficiently small $\delta$, the expected limit $\Lambda(v)$. These corrections allow for a faster convergence of the FSCLE to its asymptotic values.

For the sake of simplicity we consider maps with constant slope, e.g., the shift map $F(x) = \beta x \bmod 1$, and the CML defined in Eq. (9). In this case (for $\varepsilon < 1/2$) the maximal Lyapunov exponent of the CML coincides with that of the single map [24]; i.e., $\lambda = \ln \beta$. We will limit to the case $\nu = 0$ (i.e., to the FSLE), since the extension to generic $\nu$ is straightforward. As shown in Refs. [33,35] the finite time evolution of an infinitesimal perturbation $d_0$ initially localized in $i=0$ can be expressed at time $T$ as the sum of the contributions $M(m,T)$ associated to all the paths connecting the space-time point $(i=0,t=0)$ to the point $(i=0,t=T)$, i.e.,

$$\frac{\delta x_{i=0}(T)}{d_0} = \beta^T \sum_{m=0}^{T} M(m,T), \quad (A1)$$

where $m$ is the number of “diagonal links” connecting $(i,t)$ to $(i \pm 1, t+1)$ present in the path of length $T$. Each path $[m,T]$ of length $T$ with $m$ diagonal links contributes to the above sum with a term

$$M(m,T) = N(m,T) \left( \frac{\varepsilon}{2} \right)^m (1 - \varepsilon)^{T-m}, \quad (A2)$$
where $N(m,T)$ is the multiplicity associated to each path $[m,T]$ (for more details see [35]). As can be seen from Eq. (A1) the finite time Lyapunov exponent $\lambda_T$ will be given by

$$\lambda_T = \frac{1}{T} \ln \left( \frac{\delta x_0(T)}{d_0} \right) = \ln \beta + \frac{1}{T} \ln \left| \sum_{m=0}^{T} M(m,T) \right|.$$  \hspace{1cm} (A3)

the first contribution is the asymptotic one, while the second one will vanish in the limit $T \to \infty$ and it is the finite-time correction to evaluate. This second contribution can be numerically estimated by considering the finite time evolution of the Lyapunov eigenvector \{W_i(t)\} associated to the maximal Lyapunov exponent, once it is initialized as $W_i(0) = d_0 \delta_{i,0}$. The evolution of \{W_i(t)\} in the tangent space is ruled by the following equation:

$$W_i(t+1) = \beta \left( (1 - \epsilon) W_i(t) + \frac{\epsilon}{2} [W_{i-1}(t) + W_{i+1}(t)] \right).$$  \hspace{1cm} (A4)

In order to evaluate the finite time corrections, one should iterate at the same time Eq. (A4) (with $\beta$ fixed to one) and the two replicas required for computing $\lambda(\delta)$ (see Sec. II). Then the estimation of the FSLE should be modified in the following way:

$$\lambda(\delta) = \frac{1}{m} \langle (\delta x(t), \delta x(t)) \rangle \left( \frac{1}{\tau} \ln \left( \frac{\delta x(t+\tau)}{W_i(t)} \right) \right) - \ln \left( \frac{W_i(t+\tau)}{W_i(t)} \right) \right).$$  \hspace{1cm} (A5)

The case of maps with nonconstant slope is computationally much heavier. Since for each different path the local multiplier $F'(\tilde{x}_i)$ will be different and they will depend on the particular trajectory under consideration [33,35]. As a matter of fact we have observed that if the multipliers are equally distributed among positive and negative values, the finite time corrections essentially cancel out.
